ABSTRACT: Among first experimentally discovered two-dimensional (2D) ferromagnetic materials, chromium triiodide (CrI$_3$) monolayers have attracted particular attention due to their potential applications in electronics and spintronics. However, the Curie temperature T_c of the CrI$_3$ monolayer is below room temperature, which greatly limits practical development of the devices. Herein, using density functional theory calculation, we explore how the electronic and magnetic properties of CrI$_3$ monolayers change upon adsorption of 3d transition-metal (TM) atoms (from Sc to Zn). Our results indicate that the electronic properties of the TM−CrI$_3$ system can be tuned from semiconductor to metal/half-metal/spin gapless semiconductor depending on the choice of the adsorbed TM atoms. Moreover, the adsorption can improve the ferromagnetic stability of CrI$_3$ monolayers by increasing both magnetic moments and T_c. Notably, T_c of CrI$_3$ with Sc and V adatoms can be increased by nearly a factor of 3. We suggest postsynthesis doping of 2D CrI$_3$ by deposition of TM atoms as a new route toward potential applications of TM−CrI$_3$ systems in nanoelectronic and spintronic devices.

KEYWORDS: CrI$_3$ monolayer, transition-metal adsorption, electronic properties, ferromagnetism, magnetic properties
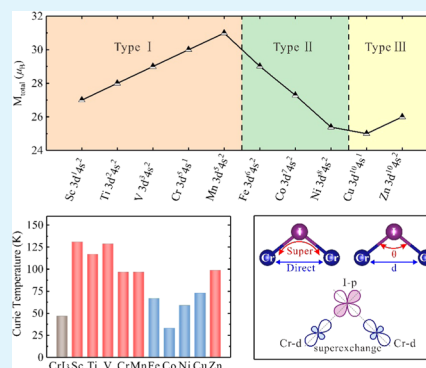

INTRODUCTION

Two-dimensional (2D) materials have been shown to possess unique and fascinating physicochemical properties pointing to their potential applications in electronics.[1−8] Unfortunately, most of these 2D materials such as graphene, boron nitride, and transition-metal dichalcogenides are nonmagnetic, which represents a significant obstacle for applications of 2D materials in spintronic devices. Hence, substantial research effort has been made to introduce magnetism in these nonmagnetic systems, such as doping,[9−11] defect,[12−14] and strain engineering,[15,16] as well as the proximity effect.[17] However, although local magnetic moments have been successfully introduced by these methods, the formation of a macroscopic state remains a big challenge. The other way to achieve 2D spintronic materials is to develop 2D materials with intrinsic ferromagnetic ordering. In 2017, the existence of the long-ranged ferromagnetic order was demonstrated in 2D CrI$_3$[18] and Cr$_2$Ge$_2$Te$_6$[19] with spins being oriented perpendicular to the material plane in the former and with arbitrary directions of spins in the latter system. After that, some other 2D ferromagnetic materials have been successfully prepared and studied, such as Fe$_3$GeTe$_2$ and CrBr$_3$.[20−23] Besides, several 2D ferromagnetic materials have been theoretically predicted, such as CrX (X = P, As),[24] GdI$_2$,[25] and FeB$_3$,[26] but not synthesized yet. These findings not only opened new avenues for the fundamental research on magnetism in systems with a reduced dimensionality but also provided exciting new opportunities for 2D spintronics.

As one of the first experimentally discovered 2D ferromagnetic materials, the CrI$_3$ monolayer has attracted especially much attention. Due to its intrinsic ferromagnetism, strong perpendicular magnetic anisotropy, giant magneto band-structure effect, distinct spin−lattice and spin−phonon coupling, and robust topological properties,[27−32] CrI$_3$ monolayer can be a potential candidate for spintronic devices. However, its Curie temperature T_c (only 45 K)[18] is much lower than room temperature, which greatly limits its practical applications. Therefore, a crucial issue is how to adjust the magnetic properties of CrI$_3$ and improve its ferromagnetic stability. Several approaches have been suggested to enhance the ferromagnetism of CrI$_3$, including electrostatic doping, electric field, defect engineering, strain, etc.[33−39] For example, the characteristics such as saturation magnetization, coercive force, and Curie temperature of the CrI$_3$ monolayer can be improved by electrostatic doping.[33] By applying an external electric field, magnetism in the CrI$_3$ bilayer can be further controlled.[35] It was predicted that surface iodine vacancies not only enhance the intrinsic ferromagnetism of the CrI$_3$ monolayer but also induce switchable electric polarization.[36]
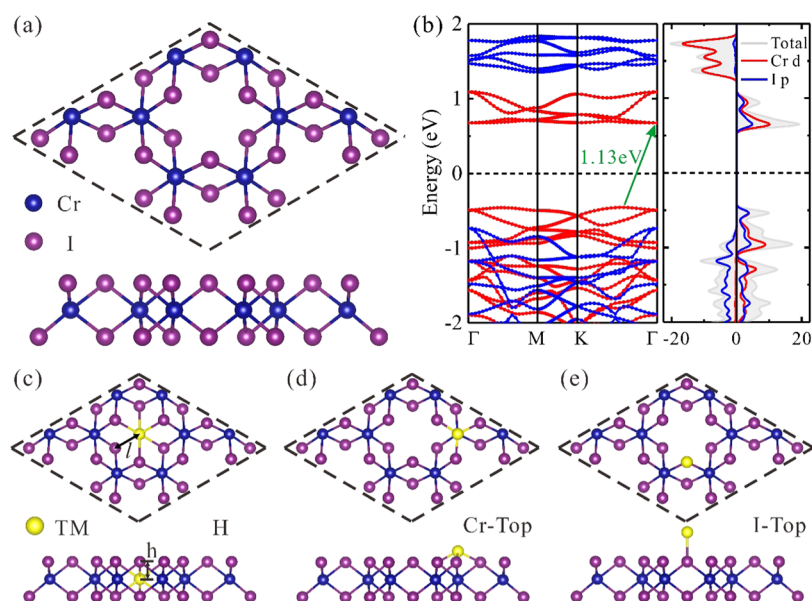

Figure 1. (a) Top and side views of the crystalline structure of the CrI_3 monolayer. (b) Spin-polarized band structure and partial density of states (PDOS) of the CrI_3 monolayer. The red and blue dotted lines denote spin-up and spin-down channels, respectively. The Fermi level is indicated by the black dashed lines. The top and side views of the crystalline structure of the system with TM atoms adsorbed in three different positions denoted as (c) H, (d) Cr-Top, and (e) I-Top. The blue, purple, and yellow balls represent Cr, I, and TM atoms, respectively.

First-principles calculations also indicated that the magnetic anisotropy energy of the CrI_3 monolayer can be increased by 47% under a 5% compressive strain.[40]

Doping is one of the most commonly used methods to tailor the electronic and magnetic properties of 2D materials.[41−43] The robust ferromagnetism was observed in Mn-doped MoS_2 synthesized by a hydrothermal method,[44] and induced magnetism was found in Re-doped $MoSe_2$ monolayer.[45] Recent theoretical studies also indicated that N doping in ReS_2 can induce the transition from nonmagnetic to tunable magnetic state.[46] Recent experimental results suggest that V-doped $MoTe_2$ is a room-temperature ferromagnetic semiconductor.[9] Alkali-metal adsorption dramatically increased the magnetic anisotropy energy of the $Cr_2Ge_2Te_6$ monolayer, leading to a significant increase in the Curie temperature.[47] The adsorption of Li atoms can enhance the ferromagnetism of CrI_3 by increasing both the magnetic moment and the Curie temperature.[48]

In this work, by means of systematic density functional theory (DFT) calculation, we investigate another way to improve the magnetic characteristics of CrI_3. Specifically, we study the influence of 3d transition-metal (TM) atoms (from Sc to Zn) adsorption on the electronic and magnetic properties of the CrI_3 monolayer. We demonstrate that electronic properties can be varied in a wide range depending on the TM atoms adsorbed on the CrI_3 monolayer. In addition, ferromagnetism in the CrI_3 monolayer can be remarkably enhanced by adsorption of TM atoms, which can be ascribed to the interplay between direct exchange and superexchange interactions. Our findings provide a promising pathway to tune the electronic properties and improve ferromagnetism in CrI_3 monolayers, which would make this material one step closer to the potential applications in nanoelectronic and spintronic devices.

COMPUTATIONAL METHOD

Our DFT calculations were carried out using the projector-augmented wave (PAW) method[49,50] implemented in Vienna Ab initio Simulation Package (VASP).[51,52] The exchange interaction and correlations were described by the generalized-gradient approximation (GGA) with the Perdew−Burke−Ernzerhof (PBE)[53] parametrization. An energy cutoff of 500 eV was set for the plane-wave basis. The Brillouin zone k-point sampling of $7 \times 7 \times 1$ grid mesh was used for geometry optimizations. The lattice constants and atomic positions were fully relaxed until the total energy and force were less than 10^{-6} eV and 0.01 eV/Å, respectively. A vacuum region of at least 18 Å along the out-of-plane direction was introduced to avoid interaction between periodic images of the system. The results were examined using the PBE + U functional. The Hubbard U values are set to be 3.0 and 2.5 eV for Cr and 3d TM atoms,[54−56] respectively. The spin−orbit coupling (SOC) was also included to examine the electronic structures of a pristine CrI_3 monolayer and magnetic moments of TM−CrI_3. Further, the hybrid functional HSE06[57] was adopted to investigate the electronic structures of Sc−CrI_3 and Mn−CrI_3. The Monte Carlo (MC) simulation based on the Ising model[34,55] was used to estimate the Curie temperature of CrI_3 and TM−CrI_3.

RESULTS AND DISCUSSION

The CrI_3 monolayer is an I−Cr−I sandwiched layer structure, where the magnetic Cr^{3+} ions form a honeycomb network in octahedral coordination, edge-sharing with six I^- ions (Figure 1a). The optimized lattice constant of the CrI_3 monolayer is 7.01 Å, the bond length between Cr and I atoms is 2.74 Å, which is in good agreement with previous reports.[48,58] It can be seen from Figure 1b that the CrI_3 monolayer is an indirect semiconductor with a band gap of 1.13 eV;[47] the valence band maximum (VBM) and the conduction band minimum (CBM) are mainly contributed by the Cr 3d and I 5p states. To evaluate the magnetic ground states of the CrI_3 monolayer, four different magnetic configurations are considered: the

ferromagnetic (FM), Néel antiferromagnetic (Néel-AFM), zigzag antiferromagnetic (zigzag-AFM), and stripy antiferromagnetic (stripy-AFM) state, as shown in Figure S1. The calculated total energies show that the FM state is energetically most favorable, indicating that ferromagnetic coupling dominates in the CrI$_3$ monolayer. The spin-density distribution of the CrI$_3$ monolayer (Figure S2) indicates that the magnetism mainly originates from magnetic moments localized on Cr atoms (3.09 μ_B per Cr atom), which is consistent with the experimental result (3.1 μ_B per Cr atom).[59] The good agreement suggests that our DFT calculations can correctly describe the geometry and properties of the CrI$_3$ monolayer. We also calculated the lattice constant, band structure, and magnetic moment of the CrI$_3$ monolayer using the PBE + U method. As shown in Table S1 and Figure S3, the lattice constant and magnetic moment of the CrI$_3$ monolayer are consistent with the results calculated by PBE. The PBE + U band gap of the CrI$_3$ monolayer (1.23 eV) only slightly differs from the PBE gap (1.13 eV). When the SOC is considered, the band gap of the CrI$_3$ monolayer is reduced to 0.89 eV, which is smaller than that calculated from PBE and PBE + U.

Having analyzed the properties of the pristine CrI$_3$, we moved on to the investigations of the adsorbed configurations and formation energies of the CrI$_3$ monolayer upon 3d TM atoms (from Sc to Zn) adsorption. A 2 × 2 × 1 CrI$_3$ supercell was chosen to represent the system (TM−CrI$_3$). Three possible adsorption sites of TM atoms on the CrI$_3$ monolayer were considered: the middle of a hexagon (H), on top of a Cr atom (Cr-Top) and on top of an I atom (I-Top), as shown in Figure 1c−e. The formation energy E_f of TM−CrI$_3$ is defined as $E_f = E_{CrI_3+TM} − E_{CrI_3} − \mu_{TM}$, where E_{CrI_3+TM} is the total energy of the CrI$_3$+TM system after structural relaxation, E_{CrI_3} is the total energy of pristine CrI$_3$, and μ_{TM} is the chemical potential of the TM atom in the isolated TM dimer ($\mu_{TM} = 1/2/E_{TM_2}$). According to our definition of formation energy, the more negative value of E_f indicates the higher stability of the adsorption configuration. Our computations showed that E_f values of TM−CrI$_3$ for the H site are more negative than that for the Cr-Top and I-Top sites (Figure 2a), suggesting that all

3d TM atoms prefer to be adsorbed on the H site. Note that all of the E_f values of TM−CrI$_3$ for the H site are negative and sizable, which indicates that TM atoms prefer to occupy positions in the atomic network of CrI$_3$ sheet rather than form dimers and likely bigger clusters. Thus, the formation of TM clusters can be avoided. In addition, the energy of TM atoms from bulk phase was also chosen as a reference to calculate the formation energy. As shown in Figure S4, TM atoms adsorption on the H site is also preferable over the Cr-Top and I-Top sites.

Besides evaluating the thermodynamic stability, we also examined the thermal stability of CrI$_3$ after TM atoms adsorption on the H site by performing DFT-based molecular dynamics (MD) simulation[42] at 300 K. The TM−CrI$_3$ structures well preserve their original framework after 5 ps (Figure S5), suggesting their thermal stability. Thus, we will focus on the H configuration in the following discussion. For the H configuration, the TM adatom forms covalent bonds with the nearest six I atoms, with the TM−I bond lengths being generally larger than 2.80 Å (see Figure 2b), varying with different TM atoms. The height of TM atoms with regard to the CrI$_3$ surface is in the range of 1.54−1.65 Å, as shown in Figure 2b. Zn−CrI$_3$ has the least negative formation energy of −0.41 eV, indicating that Zn atom bonds weakly with the CrI$_3$ monolayer. Except Zn atom, the E_f values for the other TM atoms are quite large (−1.33 to −4.92 eV), indicating that they bind strongly to the CrI$_3$ monolayer. Among them, Sc−CrI$_3$ has the most negative formation energy of −4.92 eV, which can be understood by the fact that the energy of the 3d orbital of Sc is higher than that of other 3d TM atoms.

The spin-polarized band structures of TM atoms adsorbed on CrI$_3$ monolayer are presented in Figures 3 and S6. It is evident that the adsorption of TM atoms can strongly influence the electronic properties of the CrI$_3$ monolayer. After Sc adsorption, the metallic behavior is observed in the spin-up channel, while there is a band gap of 1.76 eV in the spin-down channel, as illustrated in Figure 3a. Thus, the Sc−CrI$_3$ system shows half-metallicity and can provide 100% spin-polarized current. Examining the PDOS revealed that the bands near the Fermi level mainly come from the 3d orbitals of Sc and the neighboring Cr atoms in Sc−CrI$_3$. Similarly, the half-metal behaviors are also found for Ti, V, Cr, and Zn−CrI$_3$ (see Figure S6a−c,f). Interestingly, the spin gapless semiconductor (SGS) is expected for the adsorption of Mn atom on the CrI$_3$ monolayer, i.e., the spin-up channel has a tiny gap of 0.02 eV, while the spin-down channel displays the semiconducting character with a band gap of 1.86 eV, as shown in Figure 3b. According to the definition of Wang and Hu,[42,60] a band gap less than 0.1 eV can be termed as "gapless". Different from the case of Sc−CrI$_3$, the bands near the Fermi level are dominated by the 3d orbitals of Cr atoms adjacent to the Mn atom in Mn−CrI$_3$. The SGS is also found in Co−CrI$_3$ (see Figure S6d). For SGS materials, electrons with a particular spin can easily be excited from the valence band to the conduction band, giving rise to 100% spin-polarized current, which is desirable for the spintronic devices. As for Fe and Ni adsorption, the metallic behavior can be found in the spin-up and spin-down channels (see Figures 3c and S6e), which leads to a semiconductor-to-metal transition in the CrI$_3$ monolayer. The PDOS analysis suggests that the Fe (Ni) and Cr 3d orbitals are responsible for the metallicity. For the adsorption of Cu, the system preserves the semiconducting character with a band gap of 0.69 eV, significantly decreased as compared to

that of the pristine CrI$_3$ monolayer (1.13 eV). The VBM and CBM are mainly contributed by the 3d orbitals of Cu atom and Cr atoms, respectively, as shown in Figure 3d. The above PDOS analysis can be further substantiated by the partial charge densities of the bands near the Fermi level in Figure 3.

Taking Sc−CrI$_3$, Mn−CrI$_3$, Fe−CrI$_3$, and Cu−CrI$_3$ as examples, we examined their band structures using PBE + U functional, as shown in Figure S7. It can be seen that Sc−CrI$_3$, Mn−CrI$_3$, and Cu−CrI$_3$ remain half-metal, the SGS, and semiconducting characters, respectively, while Fe−CrI$_3$

presents the SGS behavior. Taking into account that the band structures at the Fermi level of half-metal and SGS are sensitive to the choice of the calculation method, the hybrid HSE06 functional was used to check the band structures of Sc−CrI$_3$ and Mn−CrI$_3$. As shown in Figure S8, Sc−CrI$_3$ and Mn−CrI$_3$ preserve the half-metal and SGS behaviors, respectively.

Next, we explore the effect of TM atoms on the magnetic properties of a CrI$_3$ monolayer. For simplification, the local magnetic moments of Cr, TM atoms, and the total magnetic

moments of TM−CrI$_3$ are named as M$_{Cr}$, M$_{TM}$, and M$_{total}$, respectively. As shown in Figure 4a, the M$_{Cr}$ ranges from 3.20 to 3.42 μ_B, larger than that in the pristine CrI$_3$ monolayer (3.09 μ_B). Among them, Sc−CrI$_3$ has the largest M$_{Cr}$ of 3.42 μ_B, while Ni−CrI$_3$ and Cu−CrI$_3$ have the smallest M$_{Cr}$ of 3.20 μ_B. The M$_{Cr}$ variation with TM atoms can be understood from the charge transfer in TM−CrI$_3$ (Figure 4b). Specifically, in Sc−CrI$_3$, each Cr atom has the largest electron gain of about 0.04 e, while in Ni−CrI$_3$ and Cu−CrI$_3$, each Cr atom has the least electron gain of 0.01e. On the other hand, the local magnetic moments of TM atoms (from Sc to Cu) are 0.10, 1.46, 2.57, 3.92, 4.51, 3.24, 1.92, 0.13, and 0.01 μ_B, respectively, smaller than those of the free TM atoms (Table S2). The reduction of the M$_{TM}$ well correlates with the charge transfer from the TM atom to the CrI$_3$ monolayer (Figure 4b).

To gain further insights into the total magnetic moments of TM−CrI$_3$, we examined the spin-density distributions (Figure S2). The spin-density distributions show that M$_{total}$ mainly stem from the Cr atoms and partly from the TM atoms in TM−CrI$_3$. The M$_{total}$ first increases and then decreases with increasing the TM atomic number, which exhibits a "volcano" curve, as shown in Figure 4c. The overall similar trends have also been reported in TM atom-adsorbed graphene, MoSe$_2$, and phosphorene.[10,41,61] The M$_{total}$ of TM−CrI$_3$ can be divided into three types: type I (TM = Sc, Ti, V, Cr, and Mn), type II (TM = Fe, Co, and Ni), and type III (TM = Cu and Zn). For type I, the M$_{total}$ of TM−CrI$_3$ is integer and increases linearly from 27 to 31 μ_B (from Sc to Mn) in the 2 × 2 supercell. We note that the M$_{total}$ of TM−CrI$_3$ (TM = Sc, Ti, V, Cr, and Mn) is related to the number of (s + d) electrons in the outermost electron shell. For example, a Sc atom has three outermost electrons, accordingly M$_{total}$ increases by 3 μ_B with regard to that of the pristine CrI$_3$ monolayer (24 μ_B). As the number of (s + d) electrons increases from 4 to 7 (Ti to Mn), M$_{total}$ increases stepwise from 28 to 31 μ_B (Ti to Mn). Different from the case of type I, M$_{total}$ of Fe−, Co−, and Ni−CrI$_3$ is approximately linearly reduced by 2 μ_B as compared to that for earlier TMs. For Cu−CrI$_3$, the Cu atom possesses 11 outermost electrons, wherein 10 electrons fill all of the 3d orbitals, and the left one gives rise to M$_{total}$ increase by 1 μ_B with regard to that of the pristine CrI$_3$ monolayer. As for Zn−CrI$_3$, the 12 outermost electrons of Zn atom fill all of the 3d and 4s orbitals, leading to the zero magnetic moment of Zn; thus, M$_{total}$ mainly stems from Cr atoms. Furthermore, the change in the M$_{total}$ trend can also be understood from the spin polarization of TM−CrI$_3$ in the total density of states (TDOS), as shown in Figure 5. For example, the spin-polarization asymmetry of Sc−CrI$_3$ is weaker than that of Ti−CrI$_3$ (Figure 5a,b), thus M$_{total}$ of Ti−CrI$_3$ is larger. Similarly, Co−CrI$_3$ has a larger spin polarization relative to Ni−CrI$_3$ (Figure 5c,d), leading to a larger value of M$_{total}$. The M$_{total}$ values of Sc−, Mn−, Fe−, and Cu−CrI$_3$ calculated by the PBE + U method without and with SOC are nearly the same as those obtained by the PBE method (Table S3), indicating that the magnetic moments are not much influenced by the on-site Coulombic interaction of localized electrons and the SOC effect.

We further explore the impact of TM atoms on the FM stability of a CrI$_3$ monolayer. The energy difference between the Néel-AFM and FM states ($E_{ex} = E(\text{Néel-AFM}) − E(\text{FM})$) in TM−CrI$_3$ is presented in Figure 6a. Clearly, upon the TM atom adsorption on the CrI$_3$ monolayer, the energy difference can be significantly increased. Specifically, the energy differ-

Figure 5. TDOS of (a) Sc−CrI$_3$, (b) Ti−CrI$_3$, (c) Co−CrI$_3$, and (d) Ni−CrI$_3$. The Fermi level is set at zero, denoted by the black dashed lines. The red and blue solid lines represent spin-up and spin-down channels, respectively.

ence (except Co) is between 177 and 398 meV, depending on the different TM atoms. In particular, the energy difference of Sc−CrI$_3$ can be as high as 398 meV, which is nearly 3-fold higher than that of the pristine CrI$_3$ monolayer (143 meV). These results indicate that the adsorption of TM atoms (except Co) can improve the FM stability of CrI$_3$ monolayers.

To directly evaluate the stability of FM coupling, we further investigate the Curie temperature T_c of TM−CrI$_3$. The Heisenberg spin Hamiltonian can be written as $H = −\sum_{i,j} J S_i \cdot S_j$, where J is the nearest exchange coupling parameter and $S_{i/j}$ is the spin parallel or antiparallel to the z direction. Here, the J value can be obtained from the following formula $J = E_{ex}/24S^2$, where $E_{ex} = E(\text{Néel-AFM}) − E(\text{FM})$ is the exchange energy between Néel-AFM and FM states of the system. $S = 3/2$ was chosen as the spin of each Cr atom. The calculated J value of the pristine CrI$_3$ monolayer is 2.65 meV, which is in a good agreement with the previous reports.[40] We also summarized the theoretical and experimental J values for the pristine CrI$_3$ monolayer[30,62,63] in Table S4. The J values of TM−CrI$_3$ are also listed in Table S5. From the specific heat (C_V) of the pristine CrI$_3$ monolayer presented in Figure S9, T_c is estimated to be 46 K, which is consistent with the experimental value (45 K),[18] indicating the reliability of our approach. For TM−CrI$_3$ monolayers, the T_c values (except Co) are ranged from 59 to 131 K (Figure 6b), larger than that of the pristine CrI$_3$ monolayer (46 K). Among them, the adsorption of Sc, Ti, V, Cr, Mn, and Zn can enhance the T_c value by more than 100% as to the pristine CrI$_3$ monolayer. Notably, the enhanced T_c of the CrI$_3$ monolayer upon Sc adsorption can be increased by 185%.

It is known that the FM coupling in a CrI$_3$ monolayer can be understood within the Goodenough−Kanamori−Anderson (GKA) model,[64−67] which is governed by the competition between two exchange interactions: the direct exchange and the superexchange interaction. As shown in Figure 6c, the direct exchange interaction originates from the direct electron hopping between two Cr atoms, and it shows robust AFM coupling, sensitive to the distance (d) between the adjacent Cr atoms. The superexchange interaction is mediated by an I atom and prefers FM coupling, which is governed by the Cr−I−Cr bond angle (θ). To understand the enhanced FM stability of the CrI$_3$ monolayer upon TM atom adsorption, we give the distance (d) between the adjacent Cr atoms and the
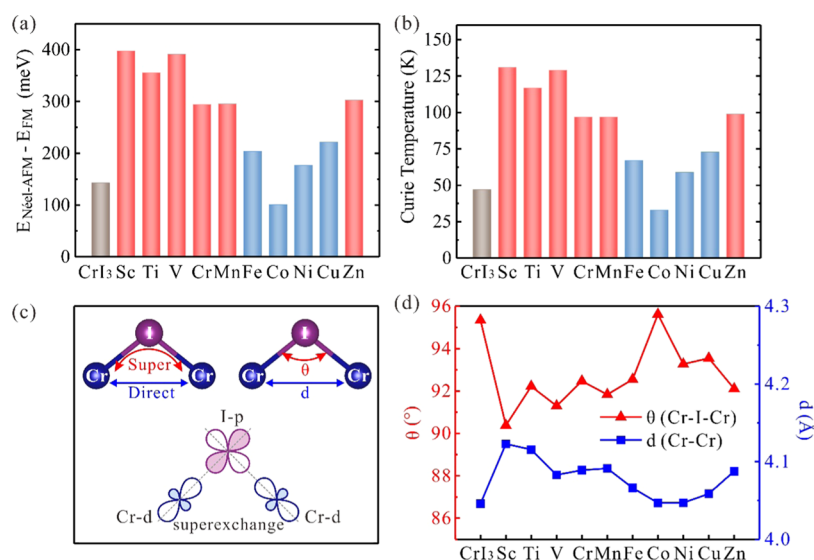

Figure 6. (a) Energy difference between the Néel-AFM and FM coupling and (b) Curie temperature of the CrI$_3$ monolayer with different TM atoms. (c) Schematic mechanism of direct exchange and superexchange interactions. (d) Cr−Cr distance and the Cr−I−Cr bond angle in the CrI$_3$ monolayer with different TM atoms.
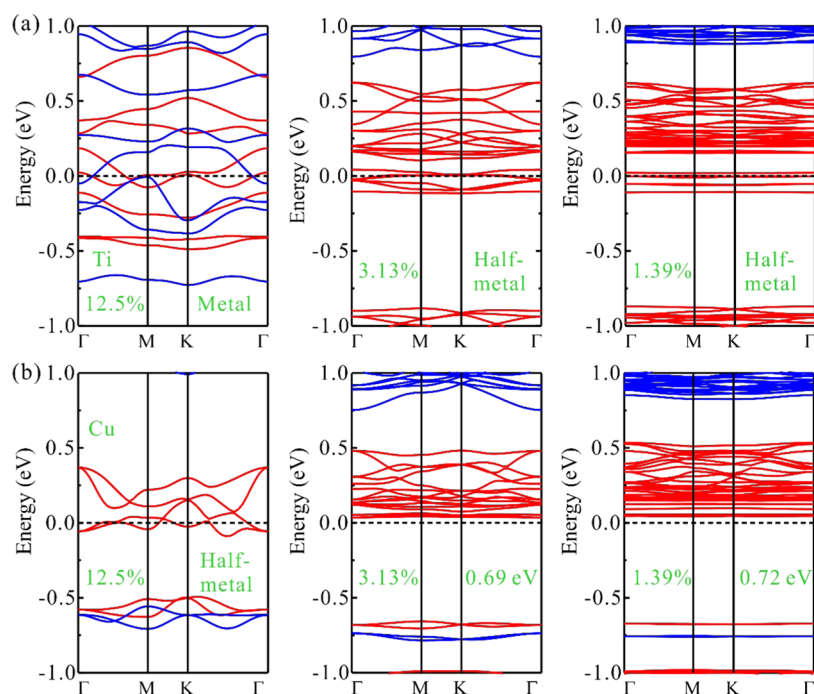

Figure 7. Spin-polarized band structures with different adatom concentrations of (a) Ti−CrI$_3$ and (b) Cu−CrI$_3$. The red and blue solid lines indicate spin-up and spin-down channels, respectively.

Cr−I−Cr bond angle (θ) in TM−CrI$_3$, as shown in Figure 6d. For the adsorption of Sc, Ti, V, Cr, Mn, and Zn atoms, the angles (θ) are closer to 90° than that of Fe, Co, Ni, and Cu adsorption. Thus, the superexchange interaction of the former is stronger than that for the latter, resulting in stronger FM coupling. On the other hand, due to larger distances (d) in Sc, Ti, V, Cr, Mn, and Zn−CrI$_3$, the AFM coupling originating from the direct exchange is weaker than that of Fe, Co, Ni, and Cu−CrI$_3$. Consequently, the FM stability in Sc, Ti, V, Cr, Mn, and Zn−CrI$_3$ is significantly enhanced. Especially for Co adsorption, the distance (d) remains almost unchanged, while the angle (θ) is slightly increased than that of the pristine CrI$_3$ monolayer, which leads to the weaker superexchange. As a

result, the FM stability of the system with Co adatoms is lower as compared to the pristine CrI$_3$ monolayer.

Furthermore, taking Ti−CrI$_3$ and Cu−CrI$_3$ as examples, we investigated the effect of the TM adatom concentration on the electronic and magnetic properties of TM−CrI$_3$. TM−CrI$_3$ with the different adatom concentrations can be constructed by choosing $1 \times 1 \times 1$, $2 \times 2 \times 1$, and $3 \times 3 \times 1$ CrI$_3$ supercells with a TM atom adsorbed, corresponding to the concentrations of 12.5, 3.13, and 1.39%, respectively. The band structures of TM−CrI$_3$ with different adatom concentrations are shown in Figure 7. It can be seen that Ti−CrI$_3$ and Cu−CrI$_3$ present metal and half-metal behaviors at a higher concentration of 12.5%. At a lower concentration (3.13 and

1.39%), Ti−CrI$_3$ and Cu−CrI$_3$ exhibit half-metal and semiconductor characters, respectively. In addition, it is found that the T_c values of Ti−CrI$_3$ and Cu−CrI$_3$ can be increased with the increase of adatom concentration, as shown in Figure S10. Specifically, the T_c values of Ti−CrI$_3$ (Cu−CrI$_3$) are 226, 116, and 91 K (136, 71, and 61 K), respectively, corresponding to the concentrations of 12.5, 3.13, and 1.39%. The results demonstrate that the electronic structure and FM stability of TM−CrI$_3$ are dependent on the adatom concentration.

CONCLUSIONS

In conclusion, we carried out systematic DFT calculations to study the electronic and magnetic properties of CrI$_3$ with various TM atoms adsorbed on its surface. Our results show that TM−CrI$_3$ system can possess various electronic properties. In particular, the CrI$_3$ monolayer with Cu adsorption remains a semiconductor with a reduced band gap of 0.69 eV, while adsorption of other 3d TM atoms leads to a semiconductor-to-metal/half-metal/spin gapless semiconductor transition. In addition, it is found that TM atom adsorption can significantly enhance the FM stability of CrI$_3$ monolayers, which is related to the interplay between direct exchange and superexchange interactions. Especially, T_c for Sc−CrI$_3$ and V−CrI$_3$ can be increased by nearly a factor of three as compared to the pristine CrI$_3$ monolayer. The deposition of TM atoms can be done after the synthesis of the material at moderate temperatures to ensure formation of adatoms in equivalent positions but avoiding their coalescence, similar to the deposition of TMs on transition- metal dichalcogenides.[9,68] This work suggests a practical route not only to tailor the electronic properties of CrI$_3$ monolayers but also to improve their FM stability. We strongly believe that this strategy can be experimentally realized in the very near future, which can greatly promote the applications of CrI$_3$ in nanoelectronic and spintronic devices.
